ABSTRACT

In this paper I am going to compare two confidential cloud services, the Confidential Consortium Framework (CCF) [5] and Nimble [2]. They both provide

Figure 1: Graphic of the CIA triade

1 INTRODUCTION

A Confidential Cloud Service is an additional service that can be applied on top of an existing cloud provider [4]. These confidential services are needed, if properties have requirements of safety, which cannot be guaranteed by a normal cloud provider.

The CIA triade, shown in Figure 1, describes three important requirements of information security [6] [1]. It contains data confidentiality, Integrity protection and high availability. Data confidentiality is keeping the data private, which is very important especially for cloud providers. Challenges are encrypting the data and protecting the keys. Integrity protection is introduced as a requirement for data confidentiality. It is the ensurance of complete and correct code that is not changed by a bad party. But these two characteristics are hard to implement although they are mandatory for cloud computing. This is, because in cloud computing the trusted computing base (TCB) gets bigger, so applications in the field of finances, medicine or governmental issues cannot afford to trust this whole TCB. High availability is required by the fact the people rely on the systems that are on the cloud. So they should work, even if failures occur.

2 BACKGROUND

Before I start with an example of a confidential cloud service some definitions must be clear to understand the following parts.

2.1 Trusted Execution Environments

A Trusted Execution Environment (TEE) is a hardware based component where critical code can be run inside a part called Enclave. The code inside this Enclave is hard to modify by malicious parties and can thus be trusted more and is therefore often be used

for confidential computing. But of course it is not impossible to change code inside a TEE, so this eventuality should also be kept in mind.

2.2 Ledger

2.3 Rollback Attacks

There exist many different attacks for cloud services like forking attacks, side channel attacks or rollback attacks. These are all important attacks that should be protected by a confidential cloud service, but in this paper I will focus on rollback attacks [3].

In this attack malicious parties save an older version of the system and apply this older version. So they "roll back" the state of the system. This can be useful for guessing encryption keys. For keys there often exist some limitations of guesses, so the key cannot get brute forced. The problem is with rolling back the state of the system a malicious member can go back to the state before the first try and try guessing again. So brute forcing the encryption key is still possible by using these attacks.

3 CCF

One example of service, that can be added on a cloud to make it confidential is the Confidential Consortium Framework (CCF) [5]. It wants to guarantee the CIA requirements on multiparty applications.

3.1 Idea

The basic idea of CCF is that an untrusted host exists and one or more untrusted users can access different replicated nodes that are responsible for the remaining communication. One of these nodes is the primary. Users can connect to any node and the specific request is either being forwarded to the primary or handled by the node itself. Operations that do not have the obligation to be handled in the primary are read-only requests. If this node fails the user can be connected to another node, if the primary fails there is a primary election that elects a new primary with certain voting criteria. Providers only need to implement the application logic and make sure to have all necessary endpoints, so that CCF can handle these. Users then only have to access the specific endpoints to use the application. In Figure 2 the structure of one node is described. The application logic gets the data from the Key-value-store which gets the data from the Consensus. The Transaction Handler stores every signature transaction in an append-only ledger that is redundant in every other node and the persistent storage. Performing the application logic inside a TEE is fundamental for the confidentiality and the integrity, replicating the transactions is necessary for the high availability.

Figure 2: Each node consists of a TEE, the untrusted host, and an interface between the host and the TEE. The TEE consists of a Key-value store, the Consensus, the Transaction Handler and the specific Application logic. The storage and the network are placed outside the TEE.

3.2 Confidentiality

3.3 Reconfiguration

Reconfiguration is the procedure when a node fails and is replaced by a new one. CCF therefore allows to add new or delete old nodes. Reconfiguration is implemented as a transaction.

3.4 Disaster Protocol

3.5 TCB

3.6 Challenges

As mentioned before CCF does not have a rollback detection, because it allows rollback attacks to happen, because it is not affecting the system. The problems are that they (1) make the assumption that the code inside the TEE cannot be changed and (2) that they put their persistent storage outside the TEEs and is therefore not protected for a rollback attack.

4 COMPARISON WITH NIMBLE

Another example for such a service is Nimble [2]. It also tries to ensure the requirement of the CIA triad, but has the focus of preventing rollback attacks.

4.1 Idea

4.2 Confidentiality

4.3 Reconfiguration

4.4 Disaster Protocol

4.5 TCB

4.6 Challenges
